Background: It is technically challenging to design compact yet sensitive miniature catheter radio frequency (RF) coils for endovascular interventional MR imaging.

Methods: In this work, a new design method for catheter RF coils is proposed based on the coaxial transmission line resonator (TLR) technique. Due to its distributed circuit, the TLR catheter coil does not need any lumped capacitors to support its resonance, which simplifies the practical design and construction and provides a straightforward technique for designing miniature catheter-mounted imaging coils that are appropriate for interventional neurovascular procedures. The outer conductor of the TLR serves as an RF shield, which prevents electromagnetic energy loss, and improves coil Q factors. It also minimizes interaction with surrounding tissues and signal losses along the catheter coil. To investigate the technique, a prototype catheter coil was built using the proposed coaxial TLR technique and evaluated with standard RF testing and measurement methods and MR imaging experiments. Numerical simulation was carried out to assess the RF electromagnetic field behavior of the proposed TLR catheter coil and the conventional lumped-element catheter coil.

Results: The proposed TLR catheter coil was successfully tuned to 64 MHz for proton imaging at 1.5 T. B1 fields were numerically calculated, showing improved magnetic field intensity of the TLR catheter coil over the conventional lumped-element catheter coil. MR images were acquired from a dedicated vascular phantom using the TLR catheter coil and also the system body coil. The TLR catheter coil is able to provide a significant signal-to-noise ratio (SNR) increase (a factor of 200 to 300) over its imaging volume relative to the body coil.

Conclusions: Catheter imaging RF coil design using the proposed coaxial TLR technique is feasible and advantageous in endovascular interventional MR imaging applications.

Introduction

The use of catheter-based radio frequency (RF) coils for interventional MRI application, while invasive, has significant advantages over using conventional external RF coils as the signal detector (1-12). An endovascular RF device offers improved detection sensitivity as a result of its proximity to the imaging target, providing high efficiency of the RF magnetic fields (i.e., $B_1$ fields) generated by the coil and improved filling factors. In endovascular intervention imaging procedures, catheter mounted RF coils must be physically small in order to meet the spatial constraints imposed by the catheter host to navigate the vessels. This poses technical challenges in designing efficient catheter coils. Conventional catheter RF coil design using lumped elements often requires a capacitor in the coil tip area to support resonance and enhance the coil’s $B_1$ fields and thus detection sensitivity. The requirement for lumped capacitors, which are usually large in size, makes it challenging to incorporate such bulky structures into miniature endovascular devices. Additionally, the long, conductive leads of the coil are part of the coil resonant circuit and can dissipate MR signals, introduce noise, and also create a safety hazard by heating surrounding tissues (12). The long, unshielded leads can also make the coil resonance unstable and consequently degrade imaging performance.

In this work, we propose a new design method of miniature catheter RF coils for endovascular interventional MR imaging. The design is based on short-circuit transmission line resonator (TLR) technology. Unlike the conventional lumped element LC resonant circuit, the transmission line is a distributed circuit, capable of providing efficient signal detection, compact coil structure, and no need to have lumped capacitors to support resonance (13-18). Due to the unique two-conductor structure, TLR RF coils have reduced radiation losses, increased quality factors, and is an unbalanced circuit allowing much more stable resonance. Furthermore, TLRs, particularly coaxial transmission lines, can shield RF fields from surrounding tissues, ultimately reducing RF field deposition, tissue heating and noise contributions from adjacent tissues along the coil structure (10,11). To investigate this new design method, a prototype catheter coil using a short-end TLR was designed and constructed for endovascular interventional MR imaging at 1.5 T. Coil parameters. Including resonance frequency, impedance matching, resonance detuning, and signal-to-noise ratio (SNR), were assessed in vitro using standard RF measurement technology. A prototype design was also validated through MR imaging experiments on a clinical 1.5 T MR scanner.

Methods

In principle, a coaxial transmission line with finite length is a resonator. When one end of the coaxial transmission line is terminated by a short-circuit, it forms a short-end or short circuit TLR. Practically the short circuit is realized by a piece of copper wire.

If the length of the copper wire is short enough, the inductance and the resistance of the wire can be ignored and the wire can be modeled as a short circuit. In this case, the coaxial transmission line structure becomes a short-ended TLR. Its equivalent circuit is shown in Figure 1. According to the equivalent circuit, the resonant frequency of a short-end coaxial transmission resonator can be expressed as (19).

$$f = \frac{c}{4L\sqrt{\varepsilon}}$$

where $c$ is the speed of light in free space; $L$ is the physical length of the TLR; and $\varepsilon_r$ is the relative permittivity of the dielectric material of the coaxial transmission line.

In this work, a shorted circuit coaxial TLR was constructed by shorting one end of a piece of 50-Ohm low loss coaxial transmission line (G01130HT, Huber + Suhner, Switzerland) which has a diameter of approximately 2.8 mm. The short circuit was implemented by using a small copper loop with a diameter of ~3–4 mm. The resistance and inductance of the copper loop at 64 MHz is negligible and thus it was modeled as a short circuit. The resonator's other end, which is open, was connected to the feeding circuit, including tuning and matching components and also a detuning circuit containing PIN diodes. With the detuning function, the catheter coil is able to be used in a platform of body coil transmit and catheter coil receive. At the shorted end of the coaxial TLR, the current reaches a maximum and the voltage goes to zero, as illustrated in Figure 1. This feature is desired in MR imaging, providing high $B_1$ sensitivity and low tissue heating at this critical location. Figure 2 shows the schematic of the short-circuit TLR and the prototype catheter coil operating at 64 MHz for proton imaging at 1.5 T. To understand the behavior of this coaxial transmission line catheter coil, the $B_1$ intensity and distribution of the coaxial TLR catheter coil was compared to a conventional lumped-element catheter coil with two parallel leads. Each circuit was modeled with the finite difference time domain (FDTD) (20) numerical calculation.
algorithm (21-26). The calculations were performed in the loaded case. The resonance frequency, impedance matching, and detuning of the prototype catheter coil were measured in vitro with a network analyzer.

The system setup for MR imaging experiment to further test the imaging abilities of the proposed design is indicated in Figure 3. A conventional whole body MR scanner (Philips Achieva, Best, the Netherlands) was used with body coil transmission. In the system configuration of body coil transmit and receive, the catheter RF coil was in the magnet but not connected to the scanner. The system body coil was connected in quadrature to generate circularly polarized $B_1$ fields for transmit and also receive. In the configuration of body coil transmit and the TLR catheter coil receive, during the transmission phase, the body coil is active and the TLR catheter coil is detuned. During the signal reception phase, the body coil is detuned by the scanner detuning device and the TLR catheter coil is tuned and active. All MR imaging experiments were performed using the prototype catheter coil with a vascular phantom (the details are shown in Figure 4). A simple gradient echo sequence was used in all imaging acquisitions. As a comparison, imaging with body coil transmit and receive was conducted using the same phantom and same acquisition parameters with the presence of the catheter coil.

Results

A prototype catheter coil was successfully constructed and tuned. Reflection coefficient S11 measurements taken on the network analyzer show a well-defined resonance of the prototype catheter coil. Its resonance frequency was successfully tuned to 64 MHz, the Larmor frequency of proton at 1.5 T, and the input impedance of the coil was matched to the system 50 Ohm with a reflection coefficient of better than −30 dB. The unbalanced circuit of the coaxial transmission resonator sufficiently suppresses the common mode currents along the catheter coil structure, yielding a stabilized resonance and impedance. $B_1$ field calculations using a FDTD algorithm indicated an expected field distribution of the circular loop current as shown in Figure 5. The $B_1$ field intensity of the proposed TLR catheter coil was 6 times stronger than that of the conventional lumped element catheter coil with the same coil size. This gain in $B_1$ results mainly from the coaxial structure that confines a large portion of the magnetic fields within the outer conduction of the coaxial transmission line.

divided by the standard deviation of the noise measured in the rectangular box shown in the images (Figure 6). The noise standard deviations of the images (Figure 6A,B) were 57.45 and 1.73, respectively. With the same acquisition parameter, catheter coil reception has an approximately 200- to 300-fold SNR gain over imaging with body coil reception. For this result, a better illustration is shown in Figure 8. In endovascular interventional imaging using the miniature catheter RF coils, imaging coverage is a critical parameter in coil design, requiring a reasonably large imaging coverage to cover the area of interest. Based on the imaging results shown in Figures 6,7, imaging coverage of this 3-mm diameter catheter coil may reach the 8–10 mm level, which is sufficient to image vessels with inner diameters of approximately 5–8 mm and the perivascular environment.

Decoupling performance of the catheter coil during body coil transmission is also critically important. Insufficient decoupling could lead to distorted MR images and degraded detection sensitivity. Figure 9 shows two images divided by the standard deviation of the noise measured in the rectangular box shown in the images (Figure 6). The noise standard deviations of the images (Figure 6A,B) were 57.45 and 1.73, respectively. With the same acquisition parameter, catheter coil reception has an approximately 200- to 300-fold SNR gain over imaging with body coil reception. For this result, a better illustration is shown in Figure 8. In endovascular interventional imaging using the miniature catheter RF coils, imaging coverage is a critical parameter in coil design, requiring a reasonably large imaging coverage to cover the area of interest. Based on the imaging results shown in Figures 6,7, imaging coverage of this 3-mm diameter catheter coil may reach the 8–10 mm level, which is sufficient to image vessels with inner diameters of approximately 5–8 mm and the perivascular environment.

Decoupling performance of the catheter coil during body coil transmission is also critically important. Insufficient decoupling could lead to distorted MR images and degraded detection sensitivity. Figure 9 shows two images divided by the standard deviation of the noise measured in the rectangular box shown in the images (Figure 6). The noise standard deviations of the images (Figure 6A,B) were 57.45 and 1.73, respectively. With the same acquisition parameter, catheter coil reception has an approximately 200- to 300-fold SNR gain over imaging with body coil reception. For this result, a better illustration is shown in Figure 8. acquired at two different positions along Z-direction (i.e., catheter axis direction (Z1 and Z2). With body coil reception (left column), nearly no elevated signal is observed in the catheter coil area (orange arrows), indicating acceptable decoupling performance between the body coil and the TLR catheter coil. Nevertheless the decoupling performance can be further improved by better design of the detuning circuit on the catheter coil. TLR, transmission line resonator.

Conclusions

A new design method of catheter RF coils for endovascular interventional MR imaging was successfully developed and validated at 1.5 T. Bench tests and MR imaging results demonstrated the feasibility and advantages of the coaxial TLR technology in achieving a miniature catheter RF coil for endovascular interventional imaging. In contrast to conventional lumped-element catheter coil designs, the coaxial transmission line does not require discrete capacitors to achieve resonance, making it more practical to build with a small physical profile. The unique feature of short-end TLRs is that their voltage and current distributions offer high B₁ fields and low E-fields near the area of the catheter tip, which is advantageous in achieving sensitive yet safe detection in endovascular imaging procedures.

One of the challenges in endovascular interventional imaging is to gain a sufficiently large imaging area to cover the vessel wall and possibly some adjacent tissues by using the size-limited catheter-mounted coil. Usually the catheter coil is formed by a loop-type circuit of which the B₁ pattern is exactly the same as that of a regular surface coil. Higher coil sensitivity or coil Q factors would help to improve the MR signals in the far end of the imaging profile, resulting in enlarged effective imaging coverage while keeping the coil loop diameter unchanged. The long leads of conventional lumped-element catheter coils are part of their resonant circuit, and have a strong interaction with the surrounding tissues along the catheter leads. In contrast, the outer conductor of the coaxial TLR serves as an RF shield and prevents electromagnetic energy loss, thus helping to achieve higher Q factors and stronger B₁ fields in the targeted imaging area. Therefore, with the same coil size, the TLR catheter coils should be able to achieve a larger imaging coverage than that of the conventional lumped-element catheter coils.

This technology may also be applicable to the design of large size coils for non-interventional imaging applications. With large coil loops, however, the lengthened coil wire will likely not be able to be treated as a short circuit, and thus would have to be modeled with appropriate inductance and resistances. The design principle should still hold and may result in improved coil performance.

The TLR concept can also be a potential method to design resonant markers (27) in tracking the catheter tip during interventional procedures. When using it as a resonant marker, the catheter coil should be a stand-alone device and would not need to be electrically connected to the MR system, allowing elimination of long catheter-shaft leads. However, a passive detuning circuit would have to be applied in that case.
