Introduction

Photoacoustic (PA) imaging (PAI), or optoacoustic imaging, is a hybrid imaging modality that combines optical absorption contrast and ultrasound image formation. In PAI, the target is excited by a short laser pulse and subsequently absorbs the photon energy, leading to a transient local temperature rise. The temperature rise induces a local pressure rise that propagates as acoustic waves. As acoustic waves generally undergo less scattering and attenuation in tissue compared with light, PAI can provide high-resolution images in both the optical (quasi)ballistic and (quasi)diffusive regimes (1,2). Based on the image formation methods, PAI can be classified into two categories: photoacoustic microscopy (PAM) and photoacoustic computed tomography (PACT). PAM uses a focused excitation light beam and/or a focused single-element ultrasonic transducer for direct image formation through position scanning (1,2). PAM has a maximum imaging depth ranging from a few hundred micrometers to a few millimeters with spatial resolution ranging from sub-micrometer to sub-millimeter (2,3). PAM can be further classified into optical-resolution PAM (OR-PAM) and acoustic-resolution PAM (AR-PAM). For both OR-PAM and AR-PAM, the axial resolution is determined by the bandwidth of the ultrasonic transducer (4). OR-PAM works in the optical (quasi)ballistic regime, whereas the light is tightly focused that it can penetrate about one optical transport mean free path (~1 mm in soft tissue). Therefore, the lateral resolution of OR-PAM is mainly determined by the optical focal spot size (4-6). The optical focusing is diffraction-limited as λ/2NA, where λ is the light wavelength, and NA is the numerical aperture of objective lens. On the contrary, in AR-PAM, the laser is loosely focused to fulfill the entire acoustic focal spot, thereby penetrating a few optical transport mean free paths, i.e., in the quasi-diffusive regime. The lateral resolution of AR-PAM is thus determined by the size of acoustic focus (4,7,8), limited by acoustic diffraction. In PACT, the object is illuminated with a wide-field laser beam in the diffusive regime, and the generated acoustic waves are detected at multiple locations or by using a multi-element transducer array. The image formed by PACT is reconstructed by an inverse algorithm. The spatial resolution of PACT is fundamentally limited by acoustic diffraction, and additionally affected by the directionality and spacing of the detector elements (9).

Recently, several studies have shown that sub-diffraction imaging of biological samples can be achieved through PAI by breaking optical-diffraction limit in the (quasi) ballistic regime or acoustic-diffraction limit in the (quasi) diffusive regime, which have opened new possibilities for fundamental biological studies. Yao et al. developed a photoimprint PAM using the intensity-dependent photobleaching effect and acquired a melanoma cell PA image with a lateral resolution of 90 nm (10). Danielli et al. reported a label-free PA nanoscopy based on the optical-absorption saturation effect and acquired a mitochondria PA image with a lateral resolution of 88 nm (11). Chaigne et al. exploited the sample-dynamics-induced inherent temporal fluctuation in the PA signals and achieved a resolution enhancement of about 1.4 over conventional...
PACT (12). Murray et al. broke the acoustic diffraction limit by implementing a blind speckle illumination and block-FISTA reconstruction algorithm and achieved a resolution close to the acoustic speckle size (13). Dean-Ben et al. also overcame the acoustic diffraction limit by incorporating rapid sequential acquisition of 3D PA images of flowing absorbing particles and further enhanced the visibility of structures under limited-view tomographic conditions (14). Conkey et al. optimized wavefront shaping with photoacoustic feedback and achieved up to ten times improvement in signal-to-noise ratio and five to six times sub-acoustic-diffraction resolution (15). In this concise review, we summarize and analyze the recent development in super-resolution (SR) PAI (SR-PAI) in both the optical (quasi)ballistic and (quasi)diffusive regime, as well as their representative applications. We also discuss the current challenges in SR-PAI and envision the potential breakthroughs.

Super-resolution OR-PAM in (quasi)ballistic regime

For OR-PAM of biological tissue at relatively superficial region, typically within one mean free path of optical scattering (<1 mm), the light propagation is in the optical (quasi)ballistic regime. Within this range, the light beam can be tightly focused on the target, and the lateral resolution is determined by the optical focal spot size, which is limited by optical diffraction, similar to other traditional optical imaging methods (16-18). To achieve super-resolution OR-PAM in the (quasi)ballistic regime, two strategies based on nonlinear optical mechanisms have been successfully exploited to overcome the optical diffraction limit (10,11).

The first strategy is reported by Yao et al., who developed photoimprint PAM (PI-PAM) based on the intensity-dependent photobleaching effect (19). Dual-pulse excitation process was implemented in this method, and its principle is illustrated in Figure 1A. The first excitation generates a PA signal from the whole excitation volume, and at the same time, bleaches more absorbers in the central diffraction-limited excitation volume than those in the peripheral region, due to the inherent illumination inhomogeneity of a Gaussian beam. In the subsequent second excitation, molecules in the bleached central area have reduced absorption and generate a smaller PA signal than that from the first excitation. Although the PA signals generated from the two excitations are linear to the excitation energy, the difference between the two PA signals, which mostly represents the signal contribution from the central area of the focus, is nonlinear to the excitation energy. This mechanism of nonlinearity endows PI-PAM with both lateral and axial resolution enhancement, and the resultant imaging resolution is determined by the ‘sharpened’ focal spot. Compared to the diffraction-limited PAM, the lateral resolution of PI-PAM is enhanced by a factor of \( \sqrt{1+b} \), where \( b \) is the power dependence of the photobleaching rate on the excitation intensity. In addition, the axial resolution of PI-PAM is improved by a factor of \( \frac{1}{\sqrt{2^{\left(1+b\right)}-1}} \) over conventional PAM. Figure 1B,C show the lateral resolution enhancement of PI-PAM over conventional OR-PAM. This imaging method can be performed on both fluorescent and nonfluorescent biological species. The major drawback of this method is the potential sample damage due to inherent photobleaching. The high frame number or excitation intensity may result in severe distortion between ‘bleached’ and ‘unbleached’ regions, thus balancing between sample distortion and SNR needs to be carefully sought. In practice, permanent photobleaching might become a concern, and photoswitchable chromophores can be introduced and cycled between bright and dark state (10,20,21). Moreover, different samples may have inconsistent resolution enhancement due to their different power dependence of photobleaching rates on the light intensity.

The second strategy attains nonlinear SR-PAM by using nonlinear thermal expansion and optical absorption saturation (11). The magnitude of PA signal is proportional to thermal expansion coefficient \( \beta(T) \), which is temperature dependent. When \( T \) is in the physiological temperature range, \( \beta(T) \approx \beta_1 + \beta_2 \cdot T \) (22). For typical biological tissues with a nanosecond laser pulse excitation, the thermal diffusion length is around tens of nanometer (23). On the other hand, the optical excitation spot is around hundreds of nanometers, which is confined by the optical diffraction limit. Therefore, there exists the nonlinear enhancement of PA signals due to the local temperature rise within a short-pulsed optical excitation. In addition, the optical absorption coefficient saturates with increasing optical fluence (24), thereby contributing a second source of nonlinearity to the PA signals. Based on these two effects, high order nonlinear PA images can be constructed by using an optical pulse train with different energies striking on the same target. Given \( M \) optical pulses in a train, PA images with up to \( N \)-th-order
(N≤M) can be formed. The nonlinear high-order PA image narrows the lateral point spread function (PSF), thereby improves the lateral resolution by a factor of \( \sqrt{N} \) over that of conventional PAM. In Danielle et al.’s work (11), a train of 1.6-ns laser pulses with pulse-to-pulse intensity modulation was used to embody this method. As illustrated in Figure 1D, at each position, four PA signals are successively excited with increasing pulse energy, then the third-order PA signals are extracted to achieve sub-diffraction resolution. In the experiment demonstration of this method, it reveals 88-nm-apart features in a single mitochondrion (Figure 1E,F). The major drawbacks of this method include the long imaging time, slow pixel-by-pixel high-order fitting, and potential heating and photobleaching damage to the sample with repeated...
excitation. Though no observable damages were reported on ex vivo cells, shorter pulses with lower energy can be used to approach the saturation intensity level with reduced photothermal damage potential (11).

**Super-resolution PA imaging in (quasi)diffusive regime**

For deep tissue imaging, it is challenging to focus light at depths beyond the optical mean free path (i.e., >1 mm). As light enters the (quasi)diffusive regime, the acoustic diffraction determines the lateral resolution of AR-PAM and PACT. To break the acoustic diffraction limit, several techniques have been exploited by probing the PA signal fluctuation (12,25), deconvolution with speckle structure illumination (13,26), localization of flowing absorbing particles (14,27), and improving optical focusing through wavefront shaping (15).

Originally developed for improving the resolution of conventional fluorescence microscopy, the statistical analysis of temporal signal fluctuations provides a simple way to obtain sub-diffraction optical resolution (28). Inspired by this approach, Chaigne et al. reported two similar methods (12,25) to achieve SR-PAI using temporal PA signal fluctuation analysis. The first method introduced multiple optical speckle illumination as the source of signal fluctuations (25). Since the speckle grain size was smaller than the acoustic focal spot size, a sub-diffraction acoustic resolution image was formed from analyzing second-order fluctuation of PA images with a number of random speckle illumination patterns. As illustrated in Figure 2A,B, this method achieved a resolution enhancement of about 1.4 times over conventional PACT. The second method relies on the fluctuation analysis of varying PA signals induced by flowing absorbing particles (12). With the natural motion of flowing particles, the fluctuation-analysis-based method is further simplified, and a long-coherence laser focus is no longer required for deep-tissue speckle illumination as in the first method. The second method can achieve a √n resolution enhancement using nth-order cumulant analysis. Nevertheless, the fluctuation-based methods are slow and likely to suffer from the natural motion artifacts for in vivo applications.
applications, including the heart beating and breathing.

Inspired by blind speckle illumination in super-resolution fluorescence imaging, Murray et al. implemented this method to break the acoustic diffraction limit in PAI in scattering media (13,29). Encoded with unknown speckle illumination patterns, the generated PA image is a convolution of the system’s PSF and the spatial product of speckle pattern and absorber distribution. Although the PA image reconstruction using this scheme is an ill-conditioned deconvolution process with a smooth kernel, Murray et al. assumed block sparsity and developed an efficient deconvolution algorithm called block-FISTA (fast iterative shrinkage-thresholding algorithm) to obtain high-resolution images. The PAT setup is similar to the fluctuation-analysis based method with speckle illumination. The experimental demonstration in Figure 2C clearly showed that this method has a much better resolution than the regular deconvoluted or averaged PA images. The 2D image formation (Figure 2D) with this method was also realized with a linear transducer array in an independent study by Hojman et al. (26).

Localization of sub-diffraction absorbers is the basis of stochastic super-resolution fluorescence microscopy (30,31), which has enabled in vivo sub-cellular biochemical research since 2006. The super-resolution localization images are constructed by superposition of a large number of isolated individual sources, which are otherwise not resolvable due to the diffraction limit. In the past two years, localization-based super-resolution ultrasound imaging has also been achieved through tracking microbubbles in deep vessels (32). Recently, two independent studies overcame the acoustic diffraction limit in PAI by localizing flowing optical absorbers (14,27). Vilov et al. performed a proof-of-principle experiment using microbeads flowing in microfluidic channels and imaged by a 15-MHz linear transducer array (27), while Dean-Ben et al. demonstrated 3D imaging of a knotted pipette filled with flowing microbeads imaged by a 4 MHz semi-spherical transducer array (14). In both studies, sparsely distributed PA point sources, i.e., microbeads, were driven through the micro-tubing or micro-channels and repeatedly captured in sequential PA images. The localization images were constructed through superposition of the central positions of point sources extracted from each PA image (Figure 3A,B,C). While the point sources were blurred in each conventional PA images due to acoustic diffraction limit, the localization image was able to break this limit and achieve sub-diffraction resolution (16,33). Nevertheless, the concept has only been demonstrated on simple phantoms without background signals or motion artifacts, and its applications for animal studies are expected to be more challenging due to reduced signal strength and image contrast.

Another way to achieve SR-PAI in deep tissue is to create a sub-acoustic-diffraction optical focus through optical wavefront shaping. Focusing light in highly scattering media has long been sought for deep-tissue imaging at optical resolution (34-37). Most of the reported wavefront shaping techniques rely on a guide-star inside the media to provide optical signal feedback (e.g., fluorescence, transmittance) for wavefront optimization. Similarly, Conkey et al. optimized optical wavefront using PA signals as the feedback (15). As illustrated in Figure 3D, the optical speckle pattern inside the ultrasound focal region was optimized using PA signal feedback through evolution algorithm, and finally reached sub-acoustic-diffraction optical focusing. When scanning the object with the optimized optical focusing, 2D PA images with sub-acoustic-diffraction resolution are formed. Using this method, Conkey et al. demonstrated a 13 μm resolution, which is much better than the conventional PAI (Figure 3E), but the speed for optimization and scanning was low. In future, with the advances in optical components and optimization algorithms, wavefront shaping in scattering media will be improved in its speed and robustness for SR-PAI in deep tissue.

Conclusions

In this concise review, we summarized various SR-PAI methods that have been explored to improve the resolution finer than either the optical or acoustic diffraction. Table 1 lists these methods and compares their mechanisms, key performance, strength and weakness. The technological advances in SR-PAI have opened new possibilities for fundamental biological studies. Compared with conventional fluorescence-based super-resolution microscopy, SR-PAI is label-free and thus can minimize the possibility of introducing image artefacts during the labeling process (38). While other label-free imaging technologies such autofluorescence-based and phase-sensitive microscopy are limited to thin samples or superficial tissues (11,39,40), SR-PAI can provide functional and structural information by imaging endogenous chromophores (e.g., hemoglobin, melanin, lipids, DNA/RNA) or exogenous chromophores (e.g., nanoparticles, organic dyes, reporter gene products) at depths far beyond the optical diffusion limit (41). Mostly
excitingly, the novel AR-PAM and PACT technologies with finer resolutions than the acoustic diffraction can potentially benefit in vivo cancer diagnostics, hemodynamics studies, and neuroscience research.

Nevertheless, challenges largely remain for deep-tissue SR-PAI. Applying blind illumination for deep tissue imaging is difficult because of the large difference between the optical speckle grain dimensions and the acoustic focal spot size. Longer optical wavelengths and higher ultrasound frequency will be beneficial to overcome the difficulty in the future (26). In optical wavefront shaping, the greatest challenge is to focus the light inside the living biological tissue with fast decorrelation motions such as blood flow and breathing. The number of input modes and genetic algorithm iterations need to be decreased, at the price of focusing quality (15). To detect PA signal fluctuation induced by flowing particles, the number of characteristic images may limit the temporal resolution of the technique (12,25,42). Similarly, the time for localizing absorbing particles depends on the frame rate and the number of pixels per image. The temporal resolution can be optimized by increasing the particle density, but it is still challenging for real-time imaging (14). Future improvements in the SR-PAI methods are needed and more phantom and in vivo validations should be performed to strengthen these methods.
